(Dated: June 30, 2008)

A puzzle in the iron-based superconductor $\text{LaFeAsO}_{1-x}\text{F}_x$ is that the magnetic moment obtained by first-principle electronic structure calculations is unexpectedly much larger than the experimentally observed one. For example, the calculated value is $\sim 2.0\mu_B$ in the mother compound, while it is $\sim 0.3\mu_B$ in experiments. We find that the puzzle is solved within the framework LDA + U by expanding the U value into a slightly negative range. We show U dependence of the obtained magnetic moment in both the undoped $x = 0.0$ and doped $x = 0.125$. These results reveal that the magnetic moment is drastically reduced when entering to the slightly negative range of U . Moreover, the negative U well explains other measurement data, e.g., lattice constants and electronic DOS at the Fermi level. We discuss possible origins of the negative U in these compounds.

PACS numbers: 74.25.Ha, 74.25.Jb, 74.70.-b

Very recently, iron based novel superconductors have attracted much attention, since its discovery may open another pathway toward the room temperature superconductor. Consequently, the superconducting critical temperature has exceeded 50K within just a few months since the start of the high- T_c race [1]. At the same time, several theoretical mechanisms have been proposed [2].

Here, we summarize the experimental results accumulated since the discovery. The typical undoped mother compound LaFeAsO shows an antiferromagnetic spin density wave (SDW) ordering after the lattice structural transition from the tetragonal to the orthorhombic structure at $\sim 150\text{K}$ when decreasing the temperature[3, 4]. The SDW disappears with doping carriers via chemical substitution of a part of O by F, and the superconducting phase instead emerges from $x \sim 0.05$ in $\text{LaFeAsO}_{1-x}\text{F}_x$. Thus, the superconductivity has a close relationship to the magnetism and the lattice distortion. In addition, the optical absorption, photoemission and NMR studies reported that a large pseudo-gap $19\text{ meV} \sim 100\text{ meV}$ opens even above the superconducting transition T_c [5, 6]. These imply an anomalous DOS suppression at the Fermi level by development of an order or other reasons. However, the clear origin still remains unsolved.

Besides the above measurement activities, the new material discovery has stimulated first-principle electronic structure calculations [7, 8, 9, 10]. Initially, inconsistent results on the magnetic structure were suggested. But, there is now a good agreement between the calculations and the experiments in respect of the magnetic and the related lattice structures. The antiferromagnetic SDW is confirmed to be the lowest energy state, in which the orthorhombic structure is stabilized by optimizing the lattice structure under the SDW magnetic order [7]. However, it is noted that there remains a big puzzle in the magnetic moment on an Fe atom in the SDW state. The moments calculated with the local-density approxima-

tion (LDA) and the generalized gradient approximation (GGA) are $\sim 1.0\mu_B$ (LDA) to $\sim 2.0\mu_B$ (GGA) [8], which is much larger than experimental data $0.2 \sim 0.35\mu_B$ obtained by the powder neutron scattering[3], Mössbauer effect[11], and muon spin relaxation [12]. Normally, the moment over-estimation in LDA(GGA) calculation is almost rare. This clearly implies that the calculations lack an unknown effect peculiar to the compounds or requires a particular correction. For example, we immediately notice that spin fluctuations always suppress the moment and two-dimensionality due to layered materials somewhat enhances the fluctuation. However, $S \sim 2$ is too large to be reduced to about $\sim 1/5$ times only by the fluctuations. Thus, this puzzle may be crucial for elucidating the superconducting mechanism. In this paper, we report how the puzzle is solved within the framework of LDA + U . We believe that the result gives a hint on the superconducting mechanism.

The Coulomb repulsion effect inside the local Fe d -orbit is listed as a missing effect. The effect is approximately treated within “LDA + U ”, $U(\equiv U_{\text{eff}})$ of which is theoretically decomposed into $U_{\text{eff}} = U - J$, where U is the on-site Coulomb repulsion (Hubbard U) and J is the atomic-orbital intra-exchange energy (Hund’s parameter) in the “simplified” framework[13]. We vary the single parameter $U_{\text{eff}} = U - J$ from a large positive value to a slightly negative one and also calculate electronic structures in another “separable” framework for U and J [14] in order to identify which parameter is more essential. We find that a slight negative U_{eff} well explains the experimental results.

The on-site Hubbard U employed in the electronic structure calculations is usually a positive value. The positiveness promotes the localized character of d -electrons and enhances the magnetic moment in the cases of magnetically ordered compounds. Since the parameter U is treated within the mean-field level in the stan-

FIG. 1: The crystal and magnetic structure in the lowest-energy state of the mother compound LaFeAsO calculated in the standard LDA ($U_{\text{eff}} = 0$). The arrows on FeAs layers denote the spin direction.

standard LDA+ U , more sophisticated methods coupled with DMFT and QMC have been also suggested [15, 16]. However, we point out that one cannot expect a drastic moment reduction irrespective of the use of such advanced methods as long as the positive large U is taken into account. In contrast, we extend the parameter U_{eff} range to a negative one. Although the negative case is not popular, it occurs in the following two cases. The Hubbard U itself is negative, and the intra-exchange J is effectively larger than the Hubbard U . The former case has been suggested by many authors in various theoretical models as discussed later. Besides such explicit reasons, a slightly negative Hubbard U simply may compensate the energy calculation errors in the LDA calculations. However, there has been just a few works taking the negative on-site Hubbard U into account within the LDA+ U framework to our knowledge [17, 18]. On the other hand, the latter case [20] may be also possible in the present compounds since J is suggested to be large [19] while U is reported to be effectively smaller than our naive expectation [21, 22]. These facts require that one flexibly chooses U_{eff} in the present compounds at least.

In this study, we employ the VASP code[23] in which the projector augmented-wave (PAW) method[24, 25] is implemented, and the lattice and the electronic structures are optimized by choosing GGA + U . The stabilities of some different magnetic structures are examined by comparing their total energy. The typical lowest-energy state at $U = 0$ for the mother compound is shown in Fig. 1, whose magnetic structure is equivalent with Ref. [3]. For the mother compound ($x = 0$), we actually adopt the $\text{La}_4\text{Fe}_4\text{As}_4\text{O}_4$ cell that have space group symmetry $Ibam$, in order to realize SDW antiferromagnetic

FIG. 2: The U_{eff} dependence for the undoped compound (solid curve) LaFeAsO and doped compound (dashed curve) $\text{LaFeAsO}_{1-x}\text{F}_x$ ($x = 0.125$) on (a) the total energy difference between the SDW (see Fig. 1) and the non-magnetic state, and (b) the SDW magnetic moment on a Fe-site, in which the experimental data (dotted curve) taken from Ref.[3] is plotted.

state as in Fig. 1. In the case of the doped compound ($x = 0.125$), we use the super cell as shown in Fig. 1, where one of O atoms is replaced by F. In our calculation, the energy cut-off for the plane-wave set is set to 500 eV, the convergence condition for electronic self-consistent loop is less than 10^{-5} eV in the total energy difference, and the structure relaxation loop is repeated until all forces on ions are smaller than 0.02 eV/Å. The grids for k points are taken as $6 \times 6 \times 6$ and $4 \times 4 \times 2$ for the undoped and doped compounds, respectively.

Let us show numerical calculation results. Firstly, we focus on the mother compound LaFeAsO. Figure 2(a) shows U_{eff} dependence of the energy difference between the non-magnetic and the stable SDW states, and Fig. 2(b) displays U_{eff} dependence of the magnetic moment in the SDW state. At $U_{\text{eff}} = 0$ where several calculations were previously made, the moment is $\sim 2.0 \mu_B$ and the energy difference is ~ 90 meV per LaFeAsO cell. These values are consistent with the previous results [7, 8, 9, 10], in which the lattice structure is optimized and the orthorhombic one is observed to be stable. For $U_{\text{eff}} > 0$, the effect of U_{eff} further develops the moment value. As expected, the positive U_{eff} stresses the localized character of d-orbital electrons, and overemphasizes the inconsistency with the experiments. On the other hand, the moment decreases with decreasing U_{eff} and coincides with the experimental results in a negative U_{eff} region. In addition, we note that the energy difference becomes very small around $U_{\text{eff}} = -1$, as in Fig. 2(a).

TABLE I: The comparison between $U = -1.0(J = 0.0)$ and $U = 0.0(J = -1.0)$ on the magnetic moment and lattice constants for the mother compound in the separable LDA+ U .

	Structure	μ [μ_B]	a [$\text{\AA}$]	b [$\text{\AA}$]	c [$\text{\AA}$]
$U - J = -1$	SDW	0.49	5.69166	5.67323	8.66216
	NM	—	5.68683	5.68703	8.64482
$U = -1 \quad J = 0$	SDW	0.50	5.69166	5.67323	8.66216
	NM	—	5.68693	5.68693	8.64482
$U = 0 \quad J = 1$	SDW	0.77	5.70995	5.65622	8.68032
	NM	—	5.68693	5.68693	8.64482
Experiment ^a	SDW	0.35	5.71043	5.68262	8.71964

^aExperimental data are taken from Refs. [3, 4]

This indicates that SDW state becomes not so strongly stable as that at $U_{\text{eff}} = 0$.

Figure 3(a) displays U_{eff} dependence of lattice constants, a , b , and c for the mother compound. The experimental values [4] are shown by horizontal dashed lines. In this paper, b is the direction along which the antiferromagnetic ordering grows. In the positive U_{eff} range, the increase of U_{eff} brings separations from the experimental results for a and b , while they show good agreements with experimental ones in the slightly negative range.

From the results as seen in Fig. 2 and 3(a), it is found that the slightly negative U_{eff} well explains the experimental results. Here, we check which parameter (U or J) is more essential in reproducing the experimental results by using the separable framework[14]. Table I is a comparison between $U = -1.0(J = 0)$ and $J = 1.0(U = 0)$ for the magnetic moment and the lattice constants. These results indicate that $U = -1.0$ is slightly closer to the experiments but it is not a conclusive difference. Moreover, the lattice constants obtained by the optimization do not differ significantly in both cases. We point out that a clear-cut determination is impossible here within the present framework.

Next, let us turn to the doped compound. The calculations are made on the supercell as shown in Fig. 1, where one of O atoms is replaced by F and $x = 0.125$ in $\text{LaFeAsO}_{1-x}\text{F}_x$. At the doping value, the compound shows the superconducting ground state. The dashed lines of Fig. 2(b) show U_{eff} dependence for the magnetic moment value in the doped compound. The data calculated at $U_{\text{eff}} = 0$ still shows the stability of the SDW state, which is equivalent with the previous literatures [7, 8]. Then, the energy difference (~ 90 meV) is too large to replace the SDW state by the non-magnetic ordered one even in the doped one. Also, the increase of U_{eff} in the positive range enhances the stability of the SDW state, which is inconsistent with the experimental results. On the other hand, the negative U_{eff} diminishes the moment resulting in the disappearance of the SDW, and the system recovers to the tetragonal lattice structure by the optimization. The behavior of the lattice

FIG. 3: The U_{eff} dependence for (a) the undoped compound LaFeAsO and (b) the doped compound $\text{LaFeAsO}_{1-x}\text{F}_x$ ($x = 0.125$) on the lattice constants a , b , c , and their ratio (a/b) in which the experimental data taken from Ref.[4] are also plotted. The solid curve and dashed curve stand for the SDW and non-magnetic states, respectively.

constants is also similar to the undoped case as seen in Fig. 3(b). At the negative range, the calculated values except for c show good agreements with experimental ones.

Figure 4 shows U_{eff} dependent features of the electronic DOS around the Fermi level in the case of the mother compound. Three cases, namely, U_{eff} positive, zero, and negative ones are given in Figs. 4(a), 4(b), and 4(c), respectively. At $U_{\text{eff}} = 0$, the gap like DOS suppression whose width is over ~ 300 meV opens, and the positive U_{eff} simply expands the width, which results in much overestimation compared to the pseudo-gap value reported by recent experiments [5, 6]. On the other hand, the slightly negative U_{eff} gives the gap value much closer to the experimental ones (~ 30 to 100 meV) as shown in Fig. 4(c).

Finally, let us discuss the mechanism of the negative U_{eff} . Firstly, we give a summary of the studies on the negative Hubbard U . Many authors have suggested their ideas on the negative Hubbard U , which are summarized in terms of theoretical target materials as follows, i) several inorganic compounds forming the charge density wave, ii) amorphous semiconductors like chalcogenide glasses, iii) conducting polymers, and iv) heavy-fermion systems. These were intensively debated in old literatures related to the local electron pairing [26]. On the other hand, more advanced studies inspired by the discovery of cuprate High- T_c superconductors have been published on several metal oxides. A famous idea originates from the charge disproportionation on the cation

FIG. 4: The electronic density of states DOS for (a) $U_{\text{eff}} = 2$, (b) $U_{\text{eff}} = 0$, and (c) $U_{\text{eff}} = -1$ in the undoped compound. $E = 0$ corresponds to the Fermi energy.

sites, which has been mainly discussed in doped superconductors based on BaBiO_3 , in which CDW occurs close to the emergence of its superconductivity [27]. In addition, the overscreening effects on the Coulomb interaction coupled with the strong correlation (due to the low carrier density) have been proposed in the context of high- T_c superconductivity mechanism [28]. If the overscreening, i.e., the attractive interaction effectively works between two electrons, then unusual softening of electronically coupled longitudinal optical (LO) phonon compared to transverse optical (TO) one has been predicted. In fact, there are several reports which confirm the LO-TO frequency inversion due to the drastic LO softening in high- T_c superconductor as well as other various metal oxides [29]. Thus, the negative Hubbard U is now not rare. But, since the effect is counterintuitive, more experimental and theoretical tasks are required. On the other hand, the idea that J is relatively effective in fixing U_{eff} may be very simple and acceptable. In this iron based superconductors, the Hubbard U may be rather small because Fe related five bands are entangled within their wide band-width. In fact, there are some experimental reports which support it [21, 22].

In conclusion, we calculated electronic structure of iron based typical superconducting compound $\text{LaFeAsO}_x\text{F}_{1-x}$ using the framework LDA+ U with expanding the range of U ($\equiv U_{\text{eff}} = U - J$) from the positive to the slightly negative range. Consequently, we found that the calculated magnetic moment, the lattice

constants, and the pseudo-gap feature shows good agreements with the experimental results in the negative U_{eff} range. We discussed some negative origin of U_{eff} in the superconductor.

The authors wish to thank S. Shamoto, A. Baron, M. Okumura, T. Koyama, A. Fujiwara, T. Maehira, and N. Hamada for illuminating discussion. The work was partially supported by the Priority Area “Physics of new quantum phases in superclean materials” (Grant No. 18043022) from the Ministry of Education, Culture, Sports, Science and Technology of Japan, and also a JAEA internal project represented by M.Kato. One of authors (M.M.) is supported by JSPS Core-to-Core Program-Strategic Research Networks, “Nanoscience and Engineering in Superconductivity (NES)”.
